Package 'genieclust'

July 22, 2025

Version 1.1.6 Date 2024-08-22 **Description** A retake on the Genie algorithm (Gagolewski, 2021 < DOI:10.1016/j.softx.2021.100722>) - a robust hierarchical clustering method (Gagolewski, Bartoszuk, Cena, 2016 < DOI:10.1016/j.ins.2016.05.003 >). Now faster and more memory efficient; determining the whole hierarchy for datasets of 10M points in low dimensional Euclidean spaces or 100K points in high-dimensional ones takes only 1-2 minutes. Allows clustering with respect to mutual reachability distances so that it can act as a noise point detector or a robustified version of 'HDBSCAN*' (that is able to detect a predefined number of clusters and hence it does not dependent on the somewhat fragile 'eps' parameter). The package also features an implementation of inequality indices (the Gini, Bonferroni index), external cluster validity measures (e.g., the normalised clustering accuracy and partition similarity scores such as the adjusted Rand, Fowlkes-Mallows, adjusted mutual information, and the pair sets index),

and internal cluster validity indices (e.g., the Calinski-Harabasz, Davies-Bouldin, Ball-Hall, Silhouette, and generalised Dunn indices). See also the 'Python' version of 'genieclust' available on 'PyPI', which

supports sparse data, more metrics, and even larger datasets.

cluster_validity

Internal Cluster Validity Measures

Description

Implementation of a number of so-called cluster validity indices critically reviewed in (Gagolewski, Bartoszuk, Cena, 2021). See Section 2 therein and (Gagolewski, 2022) for the respective definitions.

The greater the index value, the more *valid* (whatever that means) the assessed partition. For consistency, the Ball-Hall and Davies-Bouldin indexes as well as the within-cluster sum of squares (WCSS) take negative values.

Usage

```
calinski_harabasz_index(X, y)
dunnowa_index(
    X,
    y,
```

cluster_validity 3

```
M = 25L,
  owa_numerator = "SMin:5",
  owa_denominator = "Const"
)

generalised_dunn_index(X, y, lowercase_d, uppercase_d)

negated_ball_hall_index(X, y)

negated_davies_bouldin_index(X, y)

negated_wcss_index(X, y)

silhouette_index(X, y)

silhouette_index(X, y)

wcnn_index(X, y, M = 25L)
```

Arguments

X	numeric matrix with n rows and d columns, representing n points in a d-dimensional
	space

vector of n integer labels, representing a partition whose *quality* is to be assessed; y[i] is the cluster ID of the i-th point, $X[i,]; 1 \le y[i] \le K$, where K is the number or clusters

M number of nearest neighbours

owa_numerator, owa_denominator

single string specifying the OWA operators to use in the definition of the DuNN index; one of: "Mean", "Min", "Max", "Const", "SMin:D", "SMax:D", where D is an integer defining the degree of smoothness.

is an integer defining the degree of smoothness

lowercase_d an integer between 1 and 5, denoting $d_1, ..., d_5$ in the definition of the generalised

Dunn (Bezdek-Pal) index (numerator: min, max, and mean pairwise intracluster distance, distance between cluster centroids, weighted point-centroid distance,

respectively)

uppercase_d an integer between 1 and 3, denoting $D_1, ..., D_3$ in the definition of the gener-

alised Dunn (Bezdek-Pal) index (denominator: max and min pairwise intraclus-

ter distance, average point-centroid distance, respectively)

Value

A single numeric value (the more, the better).

```

compare_partitions

External Cluster Validity Measures and Pairwise Partition Similarity Scores

Description

The functions described in this section quantify the similarity between two label vectors x and y which represent two partitions of a set of n elements into, respectively, K and L nonempty and pairwise disjoint subsets.

For instance, x and y can represent two clusterings of a dataset with n observations specified by two vectors of labels. The functions described here can be used as external cluster validity measures,

compare_partitions 5

where we assume that x is a reference (ground-truth) partition whilst y is the vector of predicted cluster memberships.

All indices except normalized_clustering_accuracy() can act as a pairwise partition similarity score: they are symmetric, i.e., index(x, y) == index(y, x).

Each index except mi_score() (which computes the mutual information score) outputs 1 given two identical partitions. Note that partitions are always defined up to a permutation (bijection) of the set of possible labels, e.g., (1, 1, 2, 1) and (4, 4, 2, 4) represent the same 2-partition.

Usage

```
normalized_clustering_accuracy(x, y = NULL)
normalized_pivoted_accuracy(x, y = NULL)
pair_sets_index(x, y = NULL, simplified = FALSE, clipped = TRUE)
adjusted_rand_score(x, y = NULL, clipped = FALSE)
rand_score(x, y = NULL)
adjusted_fm_score(x, y = NULL, clipped = FALSE)
fm_score(x, y = NULL)
mi_score(x, y = NULL)
normalized_mi_score(x, y = NULL)
adjusted_mi_score(x, y = NULL)
normalized_confusion_matrix(x, y = NULL)
normalizing_permutation(x, y = NULL)
```

Arguments

X	an integer vector of length n (or an object coercible to) representing a K-partition of an n-set (e.g., a reference partition), or a confusion matrix with K rows and L columns (see table(x, y))
у	an integer vector of length n (or an object coercible to) representing an L-partition of the same set (e.g., the output of a clustering algorithm we wish to compare with x), or NULL (if x is an $K*L$ confusion matrix)
simplified	whether to assume E=1 in the definition of the pair sets index index, i.e., use Eq. (20) in (Rezaei, Franti, 2016) instead of Eq. (18)
clipped	whether the result should be clipped to the unit interval, i.e., [0, 1]

6 compare_partitions

Details

normalized_clustering_accuracy() (Gagolewski, 2023) is an asymmetric external cluster validity measure which assumes that the label vector x (or rows in the confusion matrix) represents the reference (ground truth) partition. It is an average proportion of correctly classified points in each cluster above the worst case scenario of uniform membership assignment, with cluster ID matching based on the solution to the maximal linear sum assignment problem; see normalized_confusion_matrix). It is given by: $\max_{\sigma} \frac{1}{K} \sum_{j=1}^{K} \frac{c_{\sigma(j),j} - c_{\sigma(j),j} / K}{c_{\sigma(j),j} - c_{\sigma(j),j} / K}$, where C is a confusion matrix with K rows and L columns, σ is a permutation of the set $\{1, \ldots, \max(K, L)\}$, and $c_{i,\cdot} = c_{i,1} + \ldots + c_{i,L}$ is the i-th row sum, under the assumption that $c_{i,j} = 0$ for i > K or j > L and 0/0 = 0.

normalized_pivoted_accuracy() is defined as $(\max_{\sigma} \sum_{j=1}^{\max(K,L)} c_{\sigma(j),j}/n-1/\max(K,L))/(1-1/\max(K,L))$, where σ is a permutation of the set $\{1,\ldots,\max(K,L)\}$, and n is the sum of all elements in C. For non-square matrices, missing rows/columns are assumed to be filled with 0s.

pair_sets_index() (PSI) was introduced in (Rezaei, Franti, 2016). The simplified PSI assumes E=1 in the definition of the index, i.e., uses Eq. (20) in the said paper instead of Eq. (18). For non-square matrices, missing rows/columns are assumed to be filled with 0s.

rand_score() gives the Rand score (the "probability" of agreement between the two partitions) and adjusted_rand_score() is its version corrected for chance, see (Hubert, Arabie, 1985): its expected value is 0 given two independent partitions. Due to the adjustment, the resulting index may be negative for some inputs.

Similarly, fm_score() gives the Fowlkes-Mallows (FM) score and adjusted_fm_score() is its adjusted-for-chance version; see (Hubert, Arabie, 1985).

mi_score(), adjusted_mi_score() and normalized_mi_score() are information-theoretic scores, based on mutual information, see the definition of AMI_{sum} and NMI_{sum} in (Vinh et al., 2010).

normalized_confusion_matrix() computes the confusion matrix and permutes its rows and columns so that the sum of the elements of the main diagonal is the largest possible (by solving the maximal assignment problem). The function only accepts $K \leq L$. The reordering of the columns of a confusion matrix can be determined by calling normalizing_permutation().

Also note that the built-in table() determines the standard confusion matrix.

Value

Each cluster validity measure is a single numeric value.

normalized_confusion_matrix() returns a numeric matrix.

normalizing_permutation() returns a vector of indexes.

```

emst_mlpack

Euclidean Minimum Spanning Tree

Description

Provides access to the implementation of the Dual-Tree Boruvka algorithm from the mlpack package (if available). It is based on kd-trees and is fast for (very) low-dimensional Euclidean spaces. For higher dimensional spaces (say, over 5 features) or other metrics, use the parallelised Prim-like algorithm implemented in mst().

Usage

```
emst_mlpack(X, leaf_size = 1, naive = FALSE, verbose = FALSE)
```

Arguments

X a numeric matrix (or an object coercible to one, e.g., a data frame with numeric-

like columns)

leaf_size size of leaves in the kd-tree, controls the trade-off between speed and memory

consumption

naive logical; whether to use the naive, quadratic-time algorithm

verbose logical; whether to print diagnostic messages

Value

An object of class mst, see mst() for details.

gclust

Hierarchical Clustering Algorithm Genie

Description

A reimplementation of *Genie* - a robust and outlier resistant clustering algorithm (see Gagolewski, Bartoszuk, Cena, 2016). The Genie algorithm is based on a minimum spanning tree (MST) of the pairwise distance graph of a given point set. Just like the single linkage, it consumes the edges of the MST in an increasing order of weights. However, it prevents the formation of clusters of highly imbalanced sizes; once the Gini index (see gini_index()) of the cluster size distribution raises above gini_threshold, a forced merge of a point group of the smallest size is performed. Its appealing

simplicity goes hand in hand with its usability; Genie often outperforms other clustering approaches on benchmark data, such as https://github.com/gagolews/clustering-benchmarks.

The clustering can now also be computed with respect to the mutual reachability distance (based, e.g., on the Euclidean metric), which is used in the definition of the HDBSCAN* algorithm (see Campello et al., 2013). If M > 1, then the mutual reachability distance m(i,j) with smoothing factor M is used instead of the chosen "raw" distance d(i,j). It holds $m(i,j) = \max(d(i,j),c(i),c(j))$, where c(i) is d(i,k) with k being the (M-1)-th nearest neighbour of i. This makes "noise" and "boundary" points being "pulled away" from each other.

The Genie correction together with the smoothing factor M > 1 (note that M = 2 corresponds to the original distance) gives a robustified version of the HDBSCAN* algorithm that is able to detect a predefined number of clusters. Hence it does not dependent on the DBSCAN's somewhat magical eps parameter or the HDBSCAN's min_cluster_size one.

Usage

```
gclust(d, ...)
## Default S3 method:
gclust(
 d,
  gini_threshold = 0.3,
  distance = c("euclidean", "l2", "manhattan", "cityblock", "l1", "cosine"),
  cast_float32 = TRUE,
  verbose = FALSE,
)
## S3 method for class 'dist'
gclust(d, gini_threshold = 0.3, verbose = FALSE, ...)
## S3 method for class 'mst'
gclust(d, gini_threshold = 0.3, verbose = FALSE, ...)
genie(d, ...)
## Default S3 method:
genie(
 d,
  gini_threshold = 0.3,
  distance = c("euclidean", "12", "manhattan", "cityblock", "11", "cosine"),
  postprocess = c("boundary", "none", "all"),
 detect_noise = M > 1L,
  cast_float32 = TRUE,
  verbose = FALSE,
)
```

```
## S3 method for class 'dist'
genie(
 d,
 k,
  gini_threshold = 0.3,
 M = 1L
  postprocess = c("boundary", "none", "all"),
  detect_noise = M > 1L,
  verbose = FALSE,
)
## S3 method for class 'mst'
genie(
  d,
  k,
  gini_threshold = 0.3,
  postprocess = c("boundary", "none", "all"),
  detect_noise = FALSE,
  verbose = FALSE,
)
```

Arguments

d a numeric matrix (or an object coercible to one, e.g., a data frame with numericlike columns) or an object of class dist, see dist or an object of class mst, see

mst().

... further arguments passed to other methods.

gini_threshold threshold for the Genie correction, i.e., the Gini index of the cluster size distri-

bution; Threshold of 1.0 disables the correction. Low thresholds highly penalise

the formation of small clusters.

distance metric used to compute the linkage, one of: "euclidean" (synonym: "12"),

"manhattan" (a.k.a. "11" and "cityblock"), "cosine".

cast_float32 logical; whether to compute the distances using 32-bit instead of 64-bit precision

floating-point arithmetic (up to 2x faster).

verbose logical; whether to print diagnostic messages and progress information.

k the desired number of clusters to detect, k = 1 with M > 1 acts as a noise point

detector.

M smoothing factor; M <= 2 gives the selected distance; otherwise, the mutual

reachability distance is used.

postprocess one of "boundary" (default), "none" or "all"; in effect only if M > 1. By

default, only "boundary" points are merged with their nearest "core" points (A point is a boundary point if it is a noise point and it's amongst its adjacent vertex's M-1 nearest neighbours). To force a classical k-partition of a data set (with

no notion of noise), choose "all".

detect_noise whether the minimum spanning tree's leaves should be marked as noise points, defaults to TRUE if M > 1 for compatibility with HDBSCAN*.

Details

Note that, as in the case of all the distance-based methods, the standardisation of the input features is definitely worth giving a try.

If d is a numeric matrix or an object of class dist, mst() will be called to compute an MST, which generally takes at most $O(n^2)$ time (the algorithm we provide is parallelised, environment variable OMP_NUM_THREADS controls the number of threads in use). However, see emst_mlpack() for a very fast alternative in the case of Euclidean spaces of (very) low dimensionality and M = 1.

Given an minimum spanning tree, the algorithm runs in $O(n\sqrt{n})$ time. Therefore, if you want to test different gini_thresholds, (or ks), it is best to explicitly compute the MST first.

According to the algorithm's original definition, the resulting partition tree (dendrogram) might violate the ultrametricity property (merges might occur at levels that are not increasing w.r.t. a between-cluster distance). gclust() automatically corrects departures from ultrametricity by applying height = rev(cummin(rev(height))).

Value

gclust() computes the whole clustering hierarchy; it returns a list of class hclust, see hclust. Use cutree to obtain an arbitrary k-partition.

genie() returns a k-partition - a vector with elements in 1,...,k, whose i-th element denotes the i-th input point's cluster identifier. Missing values (NA) denote noise points (if detect_noise is TRUE).

mst() for the minimum spanning tree routines.

adjusted_rand_score() (amongst others) for external cluster validity measures (partition similarity scores).

12 inequality

Examples

```
library("datasets")
data("iris")
X <- iris[1:4]
h <- gclust(X)
y_pred <- cutree(h, 3)
y_test <- iris[,5]
plot(iris[,2], iris[,3], col=y_pred,
    pch=as.integer(iris[,5]), asp=1, las=1)
adjusted_rand_score(y_test, y_pred)
pair_sets_index(y_test, y_pred)
# Fast for low-dimensional Euclidean spaces:
# h <- gclust(emst_mlpack(X))</pre>
```

inequality

Inequality Measures

Description

gini_index() gives the normalised Gini index, bonferroni_index() implements the Bonferroni index, and devergottini_index() implements the De Vergottini index.

Usage

```
gini_index(x)
bonferroni_index(x)
devergottini_index(x)
```

Arguments

Х

numeric vector of non-negative values

Details

These indices can be used to quantify the "inequality" of a numeric sample. They can be conceived as normalised measures of data dispersion. For constant vectors (perfect equity), the indices yield values of 0. Vectors with all elements but one equal to 0 (perfect inequality), are assigned scores of 1. They follow the Pigou-Dalton principle (are Schur-convex): setting $x_i = x_i - h$ and $x_j = x_j + h$ with h > 0 and $x_i - h \ge x_j + h$ (taking from the "rich" and giving to the "poor") decreases the inequality

These indices have applications in economics, amongst others. The Genie clustering algorithm uses the Gini index as a measure of the inequality of cluster sizes.

inequality 13

The normalised Gini index is given by:

$$G(x_1, \dots, x_n) = \frac{\sum_{i=1}^n (n-2i+1)x_{\sigma(n-i+1)}}{(n-1)\sum_{i=1}^n x_i},$$

The normalised Bonferroni index is given by:

$$B(x_1,\ldots,x_n) = \frac{\sum_{i=1}^n (n - \sum_{j=1}^i \frac{n}{n-j+1}) x_{\sigma(n-i+1)}}{(n-1) \sum_{i=1}^n x_i}.$$

The normalised De Vergottini index is given by:

$$V(x_1, \dots, x_n) = \frac{1}{\sum_{i=2}^n \frac{1}{i}} \left(\frac{\sum_{i=1}^n \left(\sum_{j=i}^n \frac{1}{j} \right) x_{\sigma(n-i+1)}}{\sum_{i=1}^n x_i} - 1 \right).$$

Here, σ is an ordering permutation of (x_1, \ldots, x_n) .

Time complexity: O(n) for sorted (increasingly) data. Otherwise, the vector will be sorted.

Value

The value of the inequality index, a number in [0, 1].

```

mst

Minimum Spanning Tree of the Pairwise Distance Graph

Description

An parallelised implementation of a Jarnik (Prim/Dijkstra)-like algorithm for determining a(*) minimum spanning tree (MST) of a complete undirected graph representing a set of n points with weights given by a pairwise distance matrix.

(*) Note that there might be multiple minimum trees spanning a given graph.

Usage

```
mst(d, ...)
## Default S3 method:
mst(
    d,
    distance = c("euclidean", "12", "manhattan", "cityblock", "11", "cosine"),
    M = 1L,
    cast_float32 = TRUE,
    verbose = FALSE,
    ...
)

## S3 method for class 'dist'
mst(d, M = 1L, verbose = FALSE, ...)
```

Arguments

d	either a numeric matrix (or an object coercible to one, e.g., a data frame with numeric-like columns) or an object of class dist, see dist
	further arguments passed to or from other methods
distance	metric used to compute the linkage, one of: "euclidean" (synonym: "12"), "manhattan" (a.k.a. "11" and "cityblock"), "cosine"
М	smoothing factor; $M=1$ gives the selected distance; otherwise, the mutual reachability distance is used
cast_float32	logical; whether to compute the distances using 32-bit instead of 64-bit precision floating-point arithmetic (up to $2x$ faster)
verbose	logical; whether to print diagnostic messages and progress information

mst 15

Details

If d is a numeric matrix of size np, the n(n-1)/2 distances are computed on the fly, so that O(nM) memory is used.

The algorithm is parallelised; set the OMP_NUM_THREADS environment variable Sys.setenv to control the number of threads used.

Time complexity is $O(n^2)$ for the method accepting an object of class dist and $O(pn^2)$ otherwise.

If M>= 2, then the mutual reachability distance m(i,j) with smoothing factor M (see Campello et al. 2013) is used instead of the chosen "raw" distance d(i,j). It holds $m(i,j) = \max(d(i,j),c(i),c(j))$, where c(i) is d(i,k) with k being the (M-1)-th nearest neighbour of i. This makes "noise" and "boundary" points being "pulled away" from each other. Genie++ clustering algorithm (see gclust) with respect to the mutual reachability distance gains the ability to identify some observations are noise points.

Note that the case M = 2 corresponds to the original distance, but we determine the 1-nearest neighbours separately as well, which is a bit suboptimal; you can file a feature request if this makes your data analysis tasks too slow.

Value

Matrix of class mst with n-1 rows and 3 columns: from, to and dist. It holds from < to. Moreover, dist is sorted nondecreasingly. The i-th row gives the i-th edge of the MST. (from[i], to[i]) defines the vertices (in 1,...,n) and dist[i] gives the weight, i.e., the distance between the corresponding points.

The method attribute gives the name of the distance used. The Labels attribute gives the labels of all the input points.

If M > 1, the nn attribute gives the indices of the M-1 nearest neighbours of each point.
